In a recent work of Wang Kan-chang, M.I. Soloviev and others ^{/1,2,3/}, the transversal momentum and angular distribution of Λ -particle produced in high energy πN collision (momentum of incident pion ~ 7 BeV/c) have been measured, and longitudinal polarization of Λ -particle was observed. Here in this note we will show that all the characteristic features of Λ -particle produced in high energy πN collision are in good agreement with the model suggested by D.I. Blokhintsev and one of the authors (Wang Yung)^{/4/}. This model consists of two essential points:

1. The pole term corresponding to diagram of Fig. 1 gives predominant contribution.
2. The vertex (ΛNK) takes the form $1 \pm \gamma_5$. (This model does not claim the conservation of parity in strong interaction^{/5/}).

Other than energy-momentum and strangeness conservation laws, there are no other restrictions to the multiplicity of particles produced together with Λ . The theoretical results here discussed, just alike the corresponding experimental results, are almost independent of this multiplicity.

From this model, following results were obtained:

1. Optimal transversal momentum of Λ -particle ~ 400 MeV/c (almost independent of incident pion energy).
2. In center of mass system, about 14% of Λ -particles are flying forward.

These are just the characteristic kinematic features in the Λ production experiments ^{/2,7/}. Furthermore, one can also predict from this model:

3. Λ -particles are polarized in laboratory system, the direction of polarization vector coincides with direction of momentum of Λ , i.e. polarization is purely longitudinal. Moreover, the degree of polarization is

$$\bar{p} = \zeta_{\mu} = \begin{cases} +\frac{v}{c}, & \text{for } 1 + \gamma_5, \\ -\frac{v}{c}, & \text{for } 1 - \gamma_5, \end{cases}$$

where v — velocity of Λ in laboratory system.

The coefficient of asymmetry of Λ decay is:

$$a \cong -0.89^{/6/}.$$

hence we have the following table of theoretical values of $\alpha\bar{P}$:

$P_\Lambda \left(\frac{\text{MeV}}{c}\right)_{\text{lab. syst.}}$	$\alpha\bar{P}$ (from $1 + \sqrt{5}$)	αP (from $1 - \sqrt{5}$)
~ 200	-0.16	0.16
~ 600	-0.42	0.42
~ 1000	-0.59	0.59
~ 1300	-0.67	0.67

We see that, so far as cases of $P_\Lambda \leq 1200 \frac{\text{MeV}}{c}$ are concerned, this model again gives agreement with experimental results related to the polarization of Λ produced in high energy πN collision,^{/3/} if $1 + \sqrt{5}$ is taken.

As for the cases with $P_\Lambda > 1200 \text{ MeV}/c$, no definite experimental data have been given, because in identifying the Λ -particles, some difficulties of kinematical criterion arose.^{/3/} But $P_\Lambda > 1200 \text{ MeV}/c$ in laboratory system corresponds to large angle (relative to backward direction) and smaller momentum of Λ -particle in center of mass system, and according to the suggested model, the relative number of cases in this region ($P_\Lambda > 1200 \text{ MeV}/c$ in laboratory system) is much smaller than that of $P_\Lambda < 1200 \text{ MeV}/c$ region, i.e. it is probable that only a few in the 29^{/3/} not identified cases could be cases of Λ , henceforth, the model with $1 + \sqrt{5}$ is still probable to agree with polarization experiment even in the region $P_\Lambda > 1200 \text{ MeV}/c$.

The authors wish to thank D.I. Blokhintsev for valuable suggestions and V.S. Barashenkov, M.I. Soloviev for interesting discussions.
