NOTE ON ANTIFERROMAGNETIC  
GLASSER MODEL

1980

In recent papers <sup>1,2/</sup> a linear chain of classical spins with an interaction defined by the Hamiltonian

$$H = J \sum_{i=1}^N \ln(1 - \vec{S}_i \cdot \vec{S}_{i+1}) \quad (1)$$

has been studied. Glasser <sup>1/</sup> has considered an open chain of classical one-component (Ising) spins and found that the partition function, as a function of the first spin satisfies, in the thermodynamic limit, certain singular integral equation. He found an exact solution to this equation only for one non-trivial case,  $\beta J = 1$ , and was lead to the conjecture that the system undergoes an ordering transition when the end spin is held fixed at  $\mp 1$ . Next, Niemeijer and Ruijgrok <sup>2/</sup> have considered a closed chain of classical three-component (Heisenberg) spins with periodic boundary conditions and calculate partition function and correlation functions exactly. They have shown that for  $J > 0$  a phase transition is found for  $\beta J = 1$ , where both the specific heat and the magnetic susceptibility diverge. They note, however, that for the antiferromagnetic case,  $J < 0$ , the free energy is a regular function of the temperature and the specific heat and magnetic susceptibility remain finite. As we shall see, the antiferromagnetic case corresponds to the Hamiltonian

$$H = J \sum_{i=1}^N \ln(1 + \vec{S}_i \cdot \vec{S}_{i+1}) \quad (2)$$

with  $J > 0$  rather than to the Hamiltonian (1) with  $J < 0$ .

To see this, consider the following Hamiltonian for  $N$  spins with periodic boundary conditions

$$H_{\epsilon} = J \sum_{i=1}^N \ln(1 - \epsilon \vec{S}_i \cdot \vec{S}_{i+1}), \quad (3)$$

where  $J > 0$ ,  $\vec{S}_i$  are  $n$ -component classical unit vectors and  $\epsilon = \mp 1$ . We can calculate the partition function along the lines of the well-known continuous analogue of the transfer matrix method. The partition function can be written as

$$Z_N = (4\pi)^{-N} \sum_{\nu=0}^{\infty} c_{\nu} \lambda_{\nu}^N, \quad (4)$$

where  $\lambda_\nu$  are eigenvalues of the integral equation

$$\int d\vec{S}_2 (1 - \epsilon \vec{S}_1 \cdot \vec{S}_2)^{-\beta J} \psi_{\nu\mu}(\vec{S}_2) = \lambda_\nu \psi_{\nu\mu}(\vec{S}_1) \quad (5)$$

and  $\mu = 1, 2, \dots, c_\nu$  is the degeneracy of the eigenvalue  $\lambda_\nu$ . For  $n \geq 3$  the eigenfunctions of (5) are hyperspherical harmonics, while for  $n=2$  (plane rotator model) we have

$$\psi_\nu(\theta) = \begin{cases} 1/\sqrt{2\pi} & \nu = 0 \\ e^{\pm i\nu\theta} / \sqrt{\pi} & \nu \neq 0. \end{cases} \quad (6)$$

The eigenvalues of (5) (for  $n \geq 2$ ) are given by

$$\lambda_\nu = \epsilon^\nu \Pi^{\frac{n-1}{2}} 2^{n-1-K} \frac{\Gamma(\frac{n-1}{2} - K) \Gamma(\nu + K)}{\Gamma(n + \nu - 1 - K) \Gamma(K)} \text{ for } K = \beta J < \frac{n-1}{2}. \quad (7)$$

For  $K < \frac{n-1}{2}$  we have for the free energy per spin in the thermodynamic limit

$$f = kT \ln \left[ \Pi^{\frac{3-n}{2}} 2^{K+3-n} \Gamma(n-1-K) / \Gamma(\frac{n-1}{2} - K) \right]. \quad (8)$$

For  $K = \frac{n-1}{2}$  the free energy diverges and for  $K > \frac{n-1}{2}$  is complex when defined as the analytic continuation of  $f$  for  $K > \frac{n-1}{2}$ . Note that the free energy does not depend on  $\epsilon$ . It means that the free energy and the specific heat are the same for ferromagnetic as well as for antiferromagnetic case.

The specific heat per spin is

$$C = kK^2 \left[ \zeta(2, \frac{n-1}{2} - K) - \zeta(2, n-1-K) \right] \quad (K < \frac{n-1}{2}), \quad (9)$$

where  $\zeta(n, x)$  is the generalized zeta function. The critical temperature is defined by  $K_c = \frac{n-1}{2}$  and when  $T$  is lowered towards  $T_c$  the specific heat diverges as  $C \sim (T - T_c)^{-2}$  implying that its critical exponent  $a = 2$ .

It is easy to calculate the following expression for the correlation functions

$$\langle \vec{S}_i \cdot \vec{S}_{i+r} \rangle = (\lambda_1 / \lambda_0)^r = \left( \frac{\epsilon K}{n-1-K} \right)^r \quad (10)$$

One can see that for  $\epsilon = +1$  the correlations decrease monotonically with distance as for ferromagnets, while for  $\epsilon = -1$  the correlations decay in an oscillatory way with distance,

changing sign at each site, a behaviour characteristic for antiferromagnetic chains. It is useful to define correlation length  $\xi(T)$  by

$$\xi^{-1} = -\ln |\lambda_1 / \lambda_0|. \quad (11)$$

When  $T$  is lowered towards  $T_c$ , the correlation length diverges as  $\xi \sim (T - T_c)^{-1}$ , implying that  $\nu = 1$ . For the critical exponent  $\eta$  one can obtain the non-classical value 1.

The magnetic susceptibility can now be calculated from the fluctuation relation

$$\chi = \frac{\beta}{N} \sum_{i=1}^N \sum_{j=1}^N \langle \vec{S}_i \cdot \vec{S}_j \rangle \quad (12)$$

In the thermodynamic limit eq. (12) reduces to

$$\chi = \beta \frac{n-1 + (\epsilon-1)K}{n-1 - (\epsilon+1)K}. \quad (13)$$

From (13) it can be seen that the magnetic susceptibility for the ferromagnetic case, diverges with a critical exponent  $\gamma = 1$ , which is the classical value, when the temperature approaches the critical temperature from above, whereas for the antiferromagnetic case the susceptibility vanishes when  $T$  approaches  $T_c$ .

Finally, note that the scaling relation  $(2-\eta)\nu = \gamma$  is fulfilled in the present model, while the hyperscaling relation  $d\nu = 2 - a$  is violated. Note also that the critical exponents do not depend on  $n$ . The fact that the system shows a phase transition to the ordered phase as  $T \rightarrow T_c$  from above is not in contradiction with Van Hove's well-known theorem that states that there can be no phase transition in one-dimensional classical systems with non-singular potentials of finite range, since the potential we are dealing with is obviously singular. For  $T < T_c$  the model is not well defined since the free energy becomes complex. This behaviour occurs also in other models, e.g., in the Gaussian model<sup>3/</sup>.
