Об определении спина  $X^0(958)$ -мезона в реакции  $K^-p \rightarrow X^0\Lambda$

Показано, что отсутствие анизотропий в распределениях Эдейра в реакции  $K^-p \rightarrow X^0\Lambda$  при 1,75 ГэВ/с ( $\cos\theta_{c.m.} > 0,6$ ) не означает псевдоскалярности  $X^0(958)$ -мезона. Более того, указание на обратное поведение анизотропий при 1,75 ГэВ/с ( $\cos\theta_{c.m.} > 0,6$ ) в сравнении с анизотропиями при 2,18 ГэВ/с ( $\cos\theta_{c.m.} > 0,98$ ) интерпретируется как новый аргумент в пользу спина 2 для  $X^0$ -мезона. Показано, что более четкие анизотропии при 1,75 ГэВ/с можно ожидать в интервале  $0,4 \leq \cos\theta_{c.m.} \leq 0,8$ . Получено совместное распределение по всем распадным характеристикам  $X^0$ -мезона и  $\Lambda$ ; предлагается использование этого распределения для более достоверного разделения гипотез  $0^-$  и  $2^-$  для спина-четности  $X^0$ -мезона, чем в случае использования одномерных распределений Эдейра.

Работа выполнена в Лаборатории высоких энергий ОИЯИ.

About  $X^0(958)$  Spin Determination in the Reaction  $K^-p \rightarrow X^0\Lambda$

It is shown that the absence of anisotropies in the Adair distributions for the reaction  $K^-p \rightarrow X^0\Lambda$  at 1.75 GeV/c ( $\cos\theta_{c.m.} > 0.6$ ) does not imply pseudoscalarity of the  $X(958)$ -meson. Furthermore, an indication of the opposite character of the anisotropies at 1.75 GeV/c ( $\cos\theta_{c.m.} > 0.6$ ) compared to those at 2.18 GeV/c ( $\cos\theta_{c.m.} > 0.98$ ) is interpreted as a new argument in favour of the spin-2  $X^0$ -meson assignment. More pronounced anisotropies at 1.75 GeV/c can be expected in the interval  $0.4 \leq \cos\theta_{c.m.} \leq 0.8$ . The joint distribution of all the  $X^0$ -meson and  $\Lambda$ -decay characteristics has been obtained; the likelihood analysis of this distribution, instead of the one-dimensional Adair analysis, is suggested.

The investigation has been performed at the Laboratory of High Energies, JINR.

Preprint of the Joint Institute for Nuclear Research  
Dubna 1975

1. At present the ambiguity in the  $X^0(958)$  meson spin still exists,  $J^P(X^0) = 0^-$  or  $2^-$ <sup>/1/</sup> although this question emerged more than seven years ago<sup>/2/</sup>. However, the majority of physicists prefer spin parity  $0^-$  rather than  $2^-$ ; in different kinds of theoretical estimates the  $X^0$  meson is supposed to be the ninth pseudoscalar meson, it is even called the  $\eta'$ -meson. At the same time there exist the symmetry formulae<sup>/3/</sup> predicting the  $\eta'$  mass near the mass of another ninth pseudoscalar candidate - E(1420) meson. In addition, the  $2^-$  assignment needs special attention because in this case the  $X^0$ -meson Regge trajectory should have the intercept near 1 and can play a serious role in spin forces at high energies<sup>/4/</sup>.

It is now well-known<sup>/2,5/</sup> that the  $X^0$ -meson spin can be established only by studying the  $X^0$ -meson production and decay correlations\*. Such an analysis has been performed for the reaction  $K^-p \rightarrow X^0\Lambda$  in several Brookhaven HBC experiments with beam momenta 1.75 GeV/c<sup>/6/</sup>, 2.18 GeV/c<sup>/7/</sup>, 2.885 GeV/c<sup>/8/</sup>, 3.9 and 4.5 GeV/c<sup>/9/</sup> and in earlier Berkeley HBC experiments at 2.1, 2.47 and 2.65 GeV/c<sup>/10/</sup>. In all these data no significant correlations between the  $X^0$  production and decay angles were observed when averaged over all production angles. In refs.<sup>/6,7/</sup> the small production angles  $\theta_{c.m.}$  were selected ( $x = \cos\theta_{c.m.} > 0.6-0.8$ ) again without revealing

\* The Dalitz plot analysis of the  $X^0 \rightarrow \eta\pi\pi$  and  $X^0 \rightarrow \gamma\pi^+\pi^-$  decays cannot distinguish between the  $0^-$  and  $2^-$  hypotheses<sup>/1,2/</sup>.

any significant deviations from isotropy in the Adair distributions. Since a spin zero particle must decay isotropically, this fact was interpreted as a strong support for the  $0^-$  hypothesis.

However, after Ogievetsky, Tybor and Zaslavsky had remarked that an insufficient  $\theta_{c.m.}$  cut could smooth the  $\chi^0$  meson spin effects, the data<sup>/7,10/</sup> were reanalyzed in refs.<sup>/11,12/</sup>. The Adair distributions critical for solving the  $\chi^0$  meson spin alternative<sup>/5/</sup> were obtained for very small  $\chi^0$  production angles ( $x > 0.98$ ). The anisotropies in the angular ( $\cos\theta$ ) distributions were observed at 2.18 GeV/c between the  $K^-$  beam momentum ( $\vec{k}^*$ ) in the  $\chi^0$  rest frame and the decay analyzers ( $\hat{v}$ ) chosen along a) normal ( $\hat{n}$ ) to the  $\chi^0 \rightarrow \eta\pi\pi$  decay plane, b)  $\eta$  - meson momentum ( $\vec{k}$ ) in the  $\chi^0 \rightarrow \eta\pi\pi$  decay, c)  $\gamma$  - momentum ( $\vec{k}$ ) in the  $\chi^0 \rightarrow \gamma\pi\pi$  decay. The corresponding polar-equatorial ratios  $\frac{P}{E} = \frac{N(|\cos\theta| > 0.5)}{N(|\cos\theta| < 0.5)}$

shown in Table 1 have a probability (in a  $\chi^2$  sense) of a small fraction of a percent to be in agreement with isotropy<sup>/12/</sup>. Therefore, based on the angular momentum conservation only, these anisotropies essentially weaken an evidence for the possibility of the  $0^-$  spin parity  $\chi^0$  assignment coming from the Dalitz plot analysis.

As we have pointed out in ref.<sup>/13/</sup>, the absence of the anisotropies in the LBL data<sup>/14/</sup> is possibly connected with the increase of energy (LBL data at 2.1 GeV/c reveal some anisotropy<sup>/12/</sup>). We have also stressed<sup>/13/</sup> a significance of the near threshold  $K^- p \rightarrow \chi^0 \Lambda$  experiment. In such an experiment the  $\chi^0$  -meson spin projections  $\pm 2$  on the c.m.s. beam direction ( $\vec{k}$ ) should be damped, i.e., the  $\chi^0$  spin alignment and corresponding anisotropies should appear at not too small production angles. In this context it has been pointed out in ref.<sup>/6/</sup> that the cut  $x > 0.6$  should reveal the anisotropies if only s- and p-waves essentially contribute to the  $\chi^0 \Lambda$  final state. The absence of higher waves can be expected in the near threshold experiment at 1.75 GeV/c<sup>/6/</sup>. However, this experiment reveals no significant anisotropies in the Adair dis-

tributions ( $x > 0.6$ ) similar to those found at 2.18 GeV/c ( $x > 0.98$ )/<sup>11/</sup>. Furthermore, from Table 1 we see that the Polar-equatorial ratios at 1.75 GeV/c ( $x > 0.6$ ) have a rather opposite character than the corresponding ones at 2.18 GeV/c ( $x > 0.98$ ).

Later on we'll show that such a behavior of the P/E ratios at 1.75 GeV/c ( $x > 0.6$ ) can naturally be understood and, in fact, it is another argument in favour of the  $2^- X^0$  -meson spin-parity assignment.

2. The distribution over the angle  $\theta$  between the production and decay  $X^0$ -meson spin analyzers for the zero  $X^0$  spin is isotropic. If the  $X^0$ -meson spin is 2, this distribution depends on the Legendre polynomials  $P_L^L = d_{00}^L(\theta)$ ,  $L = 0, 2, 4$ , it having the following general form (see Appendix):

$$W(\cos\theta) = \frac{1}{2} \left[ 1 + \frac{10}{7} c_2 d_2^{(v)} d_{00}^2(\theta) + \frac{18}{7} c_4 d_4^{(v)} d_{00}^4(\theta) \right], \quad (1)$$

where the quantities  $c_{2,4}$  are determined by the production mechanism only. Choosing the production analyzer ( $z$ -axis) in the  $X^0$  production plane (say, along the c.m.s. beam momentum  $\vec{K}$ ) and supposing parity conservation in the production process, these quantities can be written through the normalized  $X^0$ -meson spin density matrix elements in the form

$$c_2 = \rho_{00} + \rho_{11} - 2\rho_{22}, \quad c_4 = \rho_{00} - \frac{4}{3}\rho_{11} + \frac{1}{3}\rho_{22}. \quad (2)$$

The quantities  $d_{2,4}^{(v)}$  depend on the  $X^0$  decay mechanism only. They are determined by the formulae (A.13) similar to eqs. (2), where the  $X^0$ -meson spin density matrix elements (with quantization  $\zeta$ -axis directed along decay analyzer  $\vec{v}$ ) should be averaged over the decay phase space and then normalized.

The  $X^0$ -meson spin will most clearly manifest itself in the distribution (1) if the  $X^0$ -meson production and decay analyzers are chosen in such a way that the corresponding quantities  $c_L$  and  $d_L$  achieve maximal absolute values. Note that these quantities are limited by the definition

We have calculated the decay elements  $d_L^{(v)}$  in ref./<sup>13/</sup> and analyzed the question on the best decay analyzer in ref./<sup>14/</sup>. Here we briefly summarize the results:

$X^0 \rightarrow \gamma\gamma$  decay. The only natural decay analyzer is the  $\gamma$  momentum in the  $X^0$ -meson rest frame. Bose symmetry and  $\gamma$ -quantum transversality unambiguously determine the decay matrix element (A.14) which leads to the maximal possible  $d_L$  values  $d_2 = d_4 = 1$  thus making the  $X^0 \rightarrow \gamma\gamma$  decay especially attractive.

In the three-particle  $X^0 \rightarrow \eta\pi\pi$  and  $X^0 \rightarrow \gamma\pi^+\pi^-$  decays there are three natural decay analyzers: normal  $n$  to the  $X^0$  decay plane,  $\eta$ -meson ( $\gamma$ -quantum) momentum  $\vec{k}$  in the  $X^0$  rest frame and  $\pi$ -meson momentum  $\vec{q}$  is the dipion rest frame. The matrix elements of these decays cannot be determined unambiguously; even in the lowest orbital momentum approximation they depend on free parameters. However, using the experimental  $X^0$ -decay information, the following estimates can be done (see Appendix):

$X^0 \rightarrow \eta\pi\pi$  decay:

$$d_2^{(n)} = -0.5 \div -0.8, \quad d_4^{(n)} = 0.4 \div 0.25, \quad d_2^{(k)} = d_4^{(k)} \approx 0.4,$$

$$d_2^{(q)} = d_4^{(q)} \approx 0.6. \quad (4)$$

$X^0 \rightarrow \gamma\pi^+\pi^-$  decay

$$d_2^{(n)} = 0.3 \div 0.8, \quad d_2^{(k)} = +0.3 \div -0.8, \quad d_2^{(q)} = -0.7 \div 0.5$$

$$d_4^{(n)} = 0 \div 0.3, \quad d_4^{(k)} = 0.4 \div 0.1, \quad d_4^{(q)} = 0. \quad (5)$$

The quantities  $c_L$  can vanish in the case when there is no diagonal  $X^0$ -meson spin alignment, i.e., if  $\rho_{mm} = 1/5$ ,

$m = 0, \pm 1, \pm 2$ . But in the  $\chi^0$ -meson forward production  $K^- p \rightarrow \chi^0 \Lambda$  or at threshold of this reaction, the  $\chi^0$ -meson spin projections  $\pm 2$  on the c.m.s. beam momentum  $\vec{K}$  ( $z$ -axis) are forbidden,  $\rho_{22} = 0$ . Consequently,

$$c_2 = \frac{1}{2}(1 + \rho_{00}), \quad c_4 = \frac{1}{3}(5\rho_{00} - 2) \quad (6)$$

so that the anisotropies should be presented in the distributions (1) for an arbitrary  $\rho_{00}$  value ( $c_2 \geq 1/2$ ). Using the  $d_L$  estimates (4) and (5) and the inequality  $c_2 > 0.5$  the qualitative predictions given in Table 1 for the  $\frac{P}{E}$  ratios

$$\frac{P}{E} = \frac{1 + \frac{15}{8} \langle P_2 \rangle - \frac{135}{128} \langle P_4 \rangle}{1 - \frac{15}{8} \langle P_2 \rangle + \frac{135}{128} \langle P_4 \rangle}, \quad \langle P_L \rangle = \frac{2}{7} c_L d_L^{(v)}, \quad (7)$$

can be obtained. They are in agreement with the Brookhaven-Michigan data<sup>12/</sup> at 2.18 GeV/c ( $x > 0.98$ ).

Let us now discuss the disagreement between the P/E ratios for 2.18 GeV/c ( $x > 0.98$ )<sup>12/</sup> and for 1.75 GeV/c ( $x > 0.6$ )<sup>6/</sup>. It has been pointed out in ref.<sup>6/</sup> that the cut ( $x > 0.6$ ) should be sufficient to essentially damp the  $\rho_{22}$  value assuming that only  $s$ - and  $p$ -waves are present in the final state of the reaction  $K^- p \rightarrow \chi^0 \Lambda$ . Such an assumption is quite natural in the near threshold experiment at 1.75 GeV/c and is also supported by the  $\cos\theta_{c.m.}$  distribution. This distribution

$$W(x) = \rho_{00}(x) + 2\rho_{11}(x) + 2\rho_{22}(x), \quad (8)$$

shown in Fig. 1, can be well described by the solid curve  $W(x)$  drawn in this figure;  $W(x)$  was fitted by the Legendre polynomials  $P_L(x)$  with  $L \leq 2$ <sup>6/</sup> (higher moments  $\langle P_L \rangle$ ,  $L \geq 3$  are consistent with zero within two standard deviations) thus indicating the absence of the orbital angular momentum waves with  $\ell \geq 2$ .

However, the disagreement between the P/E ratio predictions, obtained, if  $\rho_{22} = 0$ , and those P/E ratios obtained at 1.75 GeV/c ( $x > 0.6$ ) leads us to another conclu-

Fig. 1. The  $\cos\theta$  distribution for the reaction  $K^- p, \chi^0 \Lambda$  at 1.75 GeV/c /6/ c.m. for both the  $\pi^+ \pi^- \eta$  and  $\pi^+ \pi^- \gamma$  decay modes. The solid curve  $W(x)$  is the lowest Legendre

polynomial fit to this distribution:  $W(x) = \sum_{L=0,1,2} \frac{2L+1}{2} A_L P_L(x)$ ;

the dashed curve is  $\frac{2}{5} W(x)$ . Curves 1, 2, 3 and 4 describe possible  $2\rho_{22}(x)$  elements of the  $\chi^0$ -meson spin density matrix in the case when only orbital momentum waves with  $\ell \leq 2$  contribute to the  $\chi^0 \Lambda$  final state. The normalization  $\langle \rho_{22}(x) \rangle = \frac{1}{5} \langle W(x) \rangle$  is used.

sion. Namely, the waves with  $\ell \geq 2$  should essentially contribute to the  $\rho_{22}$  element thus making the cut  $x > 0.6$  insufficient for suppressing this element to the value much more smaller than 1/5. There are several facts supporting such a conclusion.

(a) Because the  $\pm 2$   $\chi^0$ -meson spin projections cannot be constructed from the  $\Lambda$  and proton spin projections only, the  $\rho_{22}$  value essentially depends on the  $\ell_z$ -component of the orbital angular momentum. Roughly speaking, the averaged  $\ell_z$ -component is proportional to the maximal transversal momentum  $p_T$  allowed by the  $x$ -cut. Therefore claiming the same  $p_T$ -cut for 1.75 GeV/c, as well as for 2.18 GeV/c ( $x > 0.98$ ,  $p_T \lesssim 100$  MeV/c), we should require  $x > 0.92$  which is a much more stronger cut than  $x > 0.6$ .

(b) The beam momentum 1.75 GeV/c corresponds to the c.m.s. energy  $\sqrt{s} = 2130$  MeV just near the strong  $K_p^-$  resonance  $\Lambda(2100) 7/2^-$  which can decay into the  $\chi^0 \Lambda$  state with the orbital momenta  $\ell = 2, 4, 6$ . Therefore, at least, a d-wave contribution should be expected in the final state of the reaction  $K_p^- \rightarrow \chi^0 \Lambda$  at 1.75 GeV/c.

(c) Despite the fact that the  $\cos\theta_{c.m.}$  distribution is well described by the lowest Legendre polynomials  $P_L(x)$ ,  $L \leq 2$ , there are  $\approx 2\sigma$  effects in the moments  $\langle P_L(x) \rangle$  for  $L = 6, 7, 8$ . A rather strong p-wave contribution also indicates that essential higher waves could be present. Besides, the waves with  $\ell \geq 2$  can contribute to the elements  $\rho_{mm}$  and cancel in their sum  $W(x) = \sum_m \rho_{mm}(x)$ .

In fact, we do not need many additional waves in order to explain the P/E ratios in the near threshold experiment at 1.75 GeV/c. Below we'll show that even the only additional d-wave contribution is enough to obtain the  $\rho_{22}$  value near 1/5 in the interval  $x > 0.6$  and thus to explain the absence of the anisotropies expected in the case of the near zero  $\rho_{22}$  value. First we note that the  $\rho_{22}$  element should contain the amplitudes with  $\ell_z \geq 1$ , i.e.,  $\rho_{22}(x) = 0$  if  $\ell^{\max} = 0$  and generally

$$\rho_{22}(x) = F_n(x) \sin^2 \theta_{c.m.}, \quad (9)$$

where  $F_n(x)$  is a polynomial in  $x$  of the order of  $n = 2\ell^{\max} - 2$ . The  $\rho_{22}$  value can be fixed from the fact that no anisotropies were seen in the overall decay angular distributions, i.e.,  $\langle \rho_{mm} \rangle \approx \frac{1}{5} \langle W \rangle$ , (10)

where  $\langle \rho \rangle = \int_{-1}^1 \rho(x) dx$ . For  $\ell^{\max} = 1$  we then have  $2\rho_{22}(x) = \frac{3}{10} \sin^2 \theta_{c.m.}$ , curve 4 in Fig. 1, yielding the averaged value  $\langle \rho_{22} \rangle = 0.05 \ll \frac{1}{5}$  in the interval  $x > 0.6$ . For  $\ell^{\max} = 2$  the  $\rho_{22}$  element cannot be determined unambiguously. In Fig. 1. we show several functions  $2\rho_{22}(x)$  normalized by the condition (10), curves 1, 2, and 3, leading to large  $\rho_{22}$  values in the interval  $x > 0.6$ . Curve 1 yields the maximal possible  $\rho_{22}$  values for  $x$  close to 1,  $\langle \rho_{22} \rangle = 0.18 \approx 1/5$  for  $x > 0.6$  ( $\langle \rho_{22} \rangle = 0.11$  for  $x > 0.8$ ); this curve also satisfies the positivity condition  $2\rho_{22}(x) \leq W(x)$ . Of course, the only additional d-wave contribution cannot explain the opposite character of the anisotropies for 2.18 GeV/c ( $x > 0.98$ ) and those for 1.75 GeV/c ( $x > 0.6$ ). Supposing the P/E ratios at 1.75 GeV/c to be statistically meaningful, the averaged  $\rho_{22}$  value in the interval  $x > 0.6$  should be larger than 1/5 ( $c_2 < 0$ ), i.e., the waves with  $\ell \geq 3$  must contribute. However, near threshold these waves cannot essentially change the qualitative  $\rho_{22}(x)$  behaviour as expected from the considerations of the waves with  $\ell \leq 2$ . The true  $x$ -dependence of the function  $2\rho_{22}(x)$  should then be close to curve 1 thus indicating  $\rho_{22} > 1/5$  ( $c_2 < 0$ ) in the interval  $0.4 \leq x \leq 0.8$ . Therefore, in this interval we can expect more pronounced anisotropies of the same character as those found for  $x > 0.6$ .

3. Based on the analysis demonstrated in the previous section, we thus come to the conclusion different from Baltay's et al in their paper<sup>6/</sup>. Namely, an indication of rather opposite anisotropies in the Adair distributions at 1.75 GeV/c ( $x > 0.6$ )<sup>6/</sup> in comparison with those found at 2.18 GeV/c ( $x > 0.98$ )<sup>11/</sup> is naturally explained and supports an evidence for the spin-2 assignment for the  $\chi^0$ -meson coming from the Adair analysis carried out in refs.<sup>11,12/</sup>

It should be stressed that not all experimental information available has been analyzed. From the 6 natural analyzers in the decays  $\chi^0 \rightarrow \eta \pi \pi$  and  $\chi^0 \rightarrow \gamma \pi^+ \pi^-$  only the 3 analyzers (see Table 1) were used in the Adair analysis even despite the fact that some time ago we pointed out to a great importance of three other analyzers<sup>13/</sup>: the

$\pi$ -meson momentum  $\vec{q}$  in the dipion rest frame for the decays  $X^0 \rightarrow \eta \pi \pi$  ( $\gamma \pi^+ \pi^-$ ) and the normal  $\hat{n}$  to the  $X^0 \rightarrow \gamma \pi^+ \pi^-$  decay plane. The use of the best decay analyzers<sup>/14/</sup> could also be very helpful. However, present knowledge of the  $X^0$ -meson decay amplitudes may be insufficient for the determination of the best analyzer.

The way for increasing the confidence level of the arguments in favour of or against the  $2^- X^0$ -meson spin-parity assignment, even without increasing the statistics available, is the likelihood analysis of the distribution (A.12) containing all the  $X^0 \Lambda$ -production and decay information. We show in Appendix that the production information is described by 30 real  $x$ -functions, being the bilinear products of 10 complex amplitudes. In a given narrow  $x$ -interval 29 normalized production (multipole) parameters could then be determined. Note that in the case of the pseudoscalar  $X^0$ -meson there is only 1 nonzero parameter describing the  $\Lambda$ -production. All other 28 production parameters should be equal to zero. This fact can be used in a preliminary simple analysis using the method of moments.

The  $X^0$ -decay information alone was actually analyzed by the likelihood fit in ref. /9/. What we suggest here is just an extension of this analysis including all the information available. Such a joint analysis should also improve the knowledge of the  $X^0$ -meson decay parameters. For the 0- and 2- likelihood ratio we expect (based on the data in Table 1) a value less than  $10^{-3}$ .

The problem of the  $X^0$ -meson spin parity is of so great importance that further experiments are necessary for its final solution /13/. Probably, the most simple experiment is a study of the Adair distribution with the aid of electronics in the reaction  $\pi^- p \rightarrow X^0 n$  /15/.

The author is much grateful to V.I.Ogievetsky, W.Tybor and A.N.Zaslavsky for very useful discussions.

## Appendix

The differential cross section of the reaction  $K^- p \rightarrow X^0 \Lambda$  can be expressed through the joint spin density matrix elements in the production  $X^0 \Lambda$  process ( $\rho_{mm'}$ ) and spin density matrix elements in the  $X^0$  and  $\Lambda$  decays ( $r_{mm}^1$  and  $r_{nn}^2$ ) determined in coordinate systems  $x_1 y_1 z_1$  and  $x_2 y_2 z_2$  in the  $X^0$  and  $\Lambda$  rest frames, respectively,

$$d\sigma = \sum_{m m'} r_{m m'}^1 r_{n n'}^2 \rho_{m m'}^{nn'}(x) dx d_a(X; 1 \dots a) d_2(\Lambda; p \pi^-), \quad (\text{A.1})$$

where  $x = \cos \theta_{c.m.}$  and the decay phase space elements are of the form

$$d_a(a; 1 \dots a) = \prod_{j=1}^a \frac{d\vec{p}_j}{2\omega_j} \delta^{(4)}(p_a - \sum_{i=1}^a p_i), \quad (\text{A.2})$$

$p_j = (\vec{p}_j, i\omega_j)$  is the 4-momentum of the particle  $j$ . With the aid of the vectors in the  $X^0$  and  $\Lambda$  decays, the coordinate systems  $\xi_1 \eta_1 \zeta_1$  and  $\xi_2 \eta_2 \zeta_2$  can be fixed. Let us denote the Euler angles of rotations  $x_i y_i z_i \rightarrow \xi_i \eta_i \zeta_i$  by  $\Omega_i = (\phi_i, \theta_i, \psi_i), i=1,2$ . The phase space elements in the two- and three-particle decays  $a \rightarrow 12$  and  $a \rightarrow 123$  can then be written in the form

$$d_2(a; 12) = \frac{k}{4m_a} d\phi d \cos \theta, \quad (\text{A.3})$$

$$d_3(a; 123) = \frac{kq}{8m_a} dm_{23} d \cos \delta d\phi d \cos \theta d\psi,$$

where  $\vec{k} = \vec{p}_1^{(a)}$  is the momentum of particle 1 in the  $a$ -rest frame;  $\vec{q} = \vec{p}_2^{(23)}$  is the momentum of particle 2 in the c.m.s. of particles 2,3;  $m_{23}$  is the effective mass of particles 2,3, and  $\delta$  is the angle between the vectors  $\vec{k}$  and  $\vec{q}$ .

Note that the decay density matrix elements are determined through the  $X^0$  and  $\Lambda$  decay amplitudes  $A_{\{\lambda\}}^i(m_i)$ ,  $i=1,2$ :

$$r_{m_i m_i'}^i = \sum_{\{\lambda\}} A_{\{\lambda\}}^{i*}(m_i') A_{\{\lambda\}}^i(m_i) \quad (\text{A.4})$$

where  $\{\lambda\}$  are the helicities of the decay particles. Under the rotation  $x_i y_i z_i \rightarrow \xi_i \eta_i \zeta_i$  the decay amplitudes are transformed with the aid of the D -functions according to the law /16/

$$A_{\{\lambda\}}^{i'}(\mu_i) = \sum_{m_i} A_{\{\lambda\}}^i(m_i) D_{m_i \mu_i}^{J_i}(\phi_i, \theta_i, \psi_i), \quad (\text{A.5})$$

$J_1 = 2$  and  $J_2 = 1/2$ . Using this transformation, the  $\Omega_i$  dependence of the distribution (A.1) can explicitly be calculated

$$d\sigma = \sum (2L_1+1)(2L_2+1) t_{L_1 M_1}^{L_2 M_2^*}(x) T_{L_1 N_1}^1 T_{L_2 N_2}^2 D_{M_1 N_1}^{L_1^*}(\Omega_1) \times \\ \times D_{M_2 N_2}^{L_2^*}(\Omega_2) dx d_\alpha(X; 1 \dots a) d_2(\Lambda; p\pi^-), \quad (\text{A.6})$$

where the multipole parameters in the production and decay are expressed through the density matrix elements by means of the Clebsch-Gordan coefficients:

$$t_{L_1 M_1}^{L_2 M_2^*}(x) = \sum_{\{m\}} \rho_{m_1 m_1}^{m_2 m_2'}(x) (2m_1' L_1 M_1 | 2m_1) (\frac{1}{2} m_2' L_2 M_2 | \frac{1}{2} m_2), \quad (\text{A.7})$$

$$T_{L_i N_i}^i = \sum_{\{\mu\}} r_{\mu_i \mu_i}^i (J_i \mu_i' L_i N_i | J_i \mu_i). \quad (\text{A.8})$$

Hermiticity of the  $\rho$ - and  $r$ -matrices implies

$$t_{L_1 -M_1}^{L_2 -M_2^*} = (-)^{M_1+M_2} t_{L_1 M_1}^{L_2 M_2}, \quad T_{L_i N_i}^{i*} = (-)^{N_i} T_{L_i -N_i}^i \quad (\text{A.9})$$

From parity conservation in the production process (assuming that the  $z_i$  -axes are chosen in the production plane) it follows

$$t_{L_1 -M_1}^{L_2 -M_2} = (-)^{L_1+M_1+L_2+M_2} t_{L_1 M_1}^{L_2 M_2} \quad (\text{A.10})$$

Note that for the Adair analysis it is useful to choose the

$z_1$  -axis along the beam momentum in the overall c.m.s. and  $z_2 = -z_1$  and  $y_1 = y_2 = \vec{k} \times \vec{p}_X$ .

Let us further fix the coordinate systems  $\xi_i \eta_i \zeta_i$ . In a two-particle decay  $a \rightarrow 12(\Lambda \rightarrow p\pi^-, X^0 \rightarrow \gamma\gamma)$  it is natural to direct the  $\zeta$  -axis along the momentum  $\vec{p}_1^{(a)}$ . Since the decay amplitudes cannot depend on the rotation around this axis (assuming the final spins are not measured), all the nondiagonal  $r$  -matrix elements should be equal to zero ( $N_i = 0$ ), and we can put  $\psi_i = 0$ . In the three-particle decays  $X^0 \rightarrow \eta \pi \pi$  and  $X^0 \rightarrow \gamma \pi^+ \pi^-$  we choose the  $\zeta$  -axis along the normal  $\hat{n}$  to the decay plane and the  $\xi$  -axis along the  $\eta$  -meson (photon) momentum  $\vec{k}$  in the  $X^0$  rest frame. Note that parity conservation in the  $X^0$  decay, in these coordinate systems, yields particularly simple relations

$$T_{L_1 N_1}^1 = 0 \quad \text{for odd } L_1 \text{ or } N_1. \quad (\text{A.11})$$

In the  $\Lambda \rightarrow p\pi^-$  decay, parity is not conserved implying the asymmetric  $\Lambda$  decay. The  $\Lambda$  asymmetry parameter  $\alpha_\Lambda = 0.646$ ;  $\alpha_\Lambda = \sqrt{3} T_{10}^2$  providing that  $T_{00}^2 = 1$ .

Using the relations (A.9-11), the distribution (A.6) can be rewritten in the form useful for calculations

$$d\sigma = \sum_{L=0,2,4} (2L+1) \{ t_{L0}^{00}(x) [ T_{L0}^1 d_{00}^L(\theta_1) + 2 \sum_{N=2, \dots, L} \text{Re } B_{LN} d_{0N}^L(\theta_1) ] +$$

$$+ 2 \sum_{M=1, \dots, L} t_{LM}^{00}(x) [ T_{L0}^1 \cos M \phi_1 d_{M0}^L(\theta_1) + \sum_{N=2, \dots, L} (\text{Re } B_{LN} \cos M \phi_1 \times$$

$$\times d_{MN}^{L+}(\theta_1) - \text{Im } B_{LN} \sin M \phi_1 d_{MN}^{L-}(\theta_1) ] +$$

$$+ 2\sqrt{3} \alpha_\Lambda \sum_{M=1, \dots, L} \text{Im } t_{LM}^{10}(x) \cos \theta_2 [ T_{L0}^1 \sin M \phi_1 d_{M0}^L(\theta_1) +$$

$$+ \sum_{N=2, \dots, L} (\text{Re } B_{LN} \sin M \phi_1 d_{MN}^{L+}(\theta_1) + \text{Im } B_{LN} \cos M \phi_1 d_{MN}^{L-}(\theta_1) ] -$$

$$\begin{aligned}
& -\sqrt{6}a_\Lambda \sum_{M=0, \pm 1, \dots, \pm L} \operatorname{Im} t_{LM}^{11}(x) \sin \theta_2 [T_{L0}^1 \sin(M\phi_1 + \phi_2) d_{M0}^L(\theta_1) + \\
& + \sum_{N=2, \dots, L} (\operatorname{Re} B_{LN} \sin(M\phi_1 + \phi_2) d_{MN}^{L+}(\theta_1) + \operatorname{Im} B_{LN} \cos(M\phi_1 + \phi_2) d_{MN}^L(\theta_1))] \times \\
& \times dx d\Omega_2 d_\alpha(X; 1 \dots a), \quad (\text{A.12})
\end{aligned}$$

where  $B_{LN} = T_{LN}^1 e^{iN\psi_1}$  and  $d_{MN}^{L\pm} = \frac{1}{2}(d_{MN}^L \pm d_{M-N}^L)$ . Production characteristics are described by 30 real functions  $t_{LM}^{00}(x)$ ,  $t_{LM}^{10}(x)$  and  $t_{LM}^{11}(x)$ ; more precisely, we have 9 elements  $t_{LM}^{00}$ ,  $L=0, 2, 4$ ,  $M=0, 1 \dots L$ , 6 elements  $\operatorname{Im} t_{LM}^{10}$ ,  $L=2, 4$ ,  $M=1, \dots, L$  and 15 elements  $\operatorname{Im} t_{LM}^{11}$ ,  $L=0, 2, 4$ ,  $M=0, \pm 1, \dots, \pm L$ . Note that in the case of the zero  $X^0$ -meson spin there are only two independent elements  $t_{00}^{00} = \rho^{+++\rho^-}$  and  $\operatorname{Im} t_{00}^{11} = -\sqrt{\frac{2}{3}}\rho^{+-}$ ; all other 28 elements are equal to zero.

Integrating (A.12) over the phase space and introducing the quantities  $d_L$  and  $c_L$

$$d_L = \pm \sqrt{\frac{7}{2}} \frac{\int T_{L0}^1 d_\alpha(X; 1 \dots a)}{\int T_{00}^1 d_\alpha(X; 1 \dots a)}, \quad c_L = \mp \sqrt{\frac{7}{2}} \frac{\int t_{L0}^{00}(x) dx}{\int t_{00}^{00}(x) dx},$$

$L = 2, 4, \quad (\text{A.13})$

we get formula (1) for the  $W(\cos \theta)$  distribution. The  $X^0$ -meson decay multipole parameters  $T_{LN}^1$  have been

\* The multipole parameters, being the bilinear products of 10 independent complex amplitudes, depend on 18 real parameters (common phase and normalization factor not included). In the collinear case  $|x|=1$ , only the 2 independent amplitudes are left and from the 30 multipole parameters only the 5 ones, i.e.,  $t_{00}^{00}$ ,  $t_{L0}^{00}$ ,  $\operatorname{Im} t_{L1}^{11}$ ,  $L=2, 4$  can be different from zero.

calculated in ref. /14/ using, however, different normalization factors. Let us briefly reproduce the calculation here.

*The  $X^0 \rightarrow \gamma\gamma$  decay.* The amplitude of this decay is unambiguously determined by the Bose-symmetry and by the  $\gamma$ -quantum transversality

$$A_{ij} = k_i [ \vec{e}^{(1)} \times \vec{e}^{(2)} ]_j, \quad (\text{A.14})$$

where  $\vec{e}^{(1,2)}$  are the  $\gamma$  polarization vectors and  $\vec{k}=k(0,0,1)$ . The tensor representation is connected with the representation of the  $X^0$ -meson spin projections on the  $\zeta$ -axis by the well-known relations:

$$\begin{aligned}
A(\pm 2) &= \frac{1}{2}(A_{11} - A_{22}) \pm \frac{i}{2}(A_{12} + A_{21}) \\
A(\pm 1) &= \mp \frac{1}{2}(A_{13} + A_{31}) - \frac{i}{2}(A_{23} + A_{32}) \\
A(0) &= \frac{1}{\sqrt{6}}(2A_{33} - A_{11} - A_{22}).
\end{aligned} \quad (\text{A.15})$$

These relations automatically pick out the symmetric and zero trace parts of the amplitudes  $A_{ij}$ . Among the amplitudes (A.14) only  $A_{33} \neq 0$ , i.e., only the  $r_{00}$  element is different from zero and according to (A.8) and (A.13), we get

$$T_{00}^1 = r_{00}, \quad T_{20}^1 = -T_{40}^1 = -\sqrt{\frac{2}{7}} r_{00}, \quad d_2 = d_4 = 1. \quad (\text{A.16})$$

*The  $X^0 \rightarrow \eta\pi\pi$  decay.* In the lowest orbital momentum approximation  $\ell_\eta=2, \ell_{\pi\pi}=0$  and  $\ell_\eta=0, \ell_{\pi\pi}=2$ , the decay amplitudes are of the form

$$A_{ij} = w_0 k_i k_j + w_2 q_i q_j, \quad (\text{A.17})$$

where  $\vec{k} = k(0,0,1)$ ,  $\vec{q} = q(\cos \delta, \sin \delta, 0)$  in the  $\xi_1 \eta_1 \zeta_1$  system. Using again (A.15) and (A.8), we obtain the decay multipole parameters

$$\begin{aligned}
T_{00} &= \frac{2}{3} [ |w_0|^2 k^4 + |w_2|^2 q^4 + 2 \operatorname{Re} w_0 w_2^* k^2 q^2 d_{00}^2(\delta) ] \\
T_{20} &= \frac{1}{3} \sqrt{\frac{2}{7}} [ |w_0|^2 k^4 + |w_2|^2 q^4 - 2 \operatorname{Re} w_0 w_2^* k^2 q^2 (1 - 2d_{00}^2(\delta)) ] \\
T_{22} &= -\frac{1}{\sqrt{21}} [ |w_0|^2 k^4 + \operatorname{Re} w_0 w_2^* k^2 q^2 + (\operatorname{Re} w_0 w_2^* k^2 q^2 + |w_2|^2 q^4) e^{2i\delta} ] \\
T_{40} &= \frac{1}{\sqrt{14}} [ \frac{1}{2} (|w_0|^2 k^4 + |w_2|^2 q^4) + \frac{1}{9} \operatorname{Re} w_0 w_2^* k^2 q^2 (5 + 4d_{00}^2(\delta)) ] \\
T_{42} &= \frac{1}{2} \sqrt{\frac{5}{3}} T_{22} \\
T_{44} &= \frac{\sqrt{5}}{12} [ |w_0|^2 k^4 + 2 \operatorname{Re} w_0 w_2^* k^2 q^2 e^{2i\delta} + |w_2|^2 q^4 e^{4i\delta} ].
\end{aligned} \tag{A.18}$$

The parameters  $w_l$  can depend on the  $m_{\pi\pi}$  mass. Supposing this dependence negligible, the only complex parameter  $w = w_2/w_0$ , is left. For the quantities  $d_L$ , we then get

$$d_2^{(n)} = -\frac{1}{2} + \frac{\operatorname{Re} w a_3}{a_1 + |w|^2 a_2}, \quad d_4^{(n)} = \frac{3}{8} + \frac{5}{12} \frac{\operatorname{Re} w a_3}{a_1 + |w|^2 a_2}, \tag{A.19}$$

where  $a_1$ ,  $a_2$  and  $a_3$  are phase space integrals over the quantities  $k^4$ ,  $q^4$  and  $k^2 q^2$ ;  $a_1 : a_2 : a_3 = 6.6 : 1 : 1.5$ . The  $d_L$  values for the decay analyzers  $\vec{k}$  and  $\vec{q}$  can be obtained by means of the rotation (A.5) /13,14/:

$$d_2^{(k)} = d_4^{(k)} = \frac{a_1}{a_1 + |w|^2 a_2}, \quad d_2^{(q)} = d_4^{(q)} = 1 - d_2^{(k)}, \tag{A.20}$$

If  $\operatorname{Re} w \leq 0$ , the extreme  $d_2$  values are equal to /14/

$$d_2^{\min} = d_2^{(n)} \approx -0.5, \quad d_2^{\max} = d_2^{(v_0)} \approx 0.86, \tag{A.21}$$

where the vector  $\vec{v}_0$  lies in the  $X^0$  decay plane:  $\vec{v}_0 = (\cos \alpha, \sin \alpha, 0)$ ; the angle  $\alpha$  is determined by the condition /14/

$$e^{2i\alpha} = \frac{T_{22}^1}{|T_{22}^1|}. \tag{A.22}$$

The numerical estimates are given for an almost purely imaginary Brookhaven experimental value of  $w^{11/}$ :  $w^{-1} = -0.02 \pm 0.05 + (0.35 \pm 0.02)i$ . The real value  $w = -4$  is however predicted by the Adler selfconsistency condition /2/. Such a discrepancy can probably be explained by an essential  $m_{\pi\pi}$  dependence of the parameter  $w_2$  resulting from the final state  $\pi\pi$ -interaction /17/.

*The  $X^0 \rightarrow \gamma \pi^+ \pi^-$  decay.* Taking into account only the M1 and E2 transition amplitudes in the dominating  $X^0 \rightarrow \gamma \rho^0$  decay channel, we can write

$$A_{ij} = \{ g_1 q_i [ \vec{k} \times \vec{e} ]_j + g_2 e_i [ \vec{k} \times \vec{q} ]_j \} f(m_{\pi\pi}), \tag{A.23}$$

where  $f(m_{\pi\pi})$  is the  $\rho^0$ -meson propagator. Here the parameters  $g_{1,2}$  are expected to be real and independent of the  $m_{\pi\pi}$  mass. Introducing a real parameter  $g = g_2/g_1$  and omitting the inessential factor  $g_1 k q f(m_{\pi\pi})$ , we get the following formulae for the decay multipole parameters

$$\begin{aligned}
T_{00} &= \frac{1}{9} [ 10 + 10g + 7g^2 - (1 + 10g + 7g^2) d_{00}^2(\delta) ] \\
T_{20} &= \frac{1}{18} \sqrt{\frac{2}{7}} [ \frac{5}{2} - 14g - 11g^2 + (2 + 14g + 11g^2) d_{00}^2(\delta) ] \\
T_{22} &= \frac{1}{4\sqrt{21}} [ 2 + 7g + 3g^2 \sin^2 \delta - (5 + 7g) e^{2i\delta} ] \\
T_{40} &= \frac{1}{9} \sqrt{\frac{2}{7}} [ -\frac{5}{4} + 2g^2 - (1 + 2g^2) d_{00}^2(\delta) ]
\end{aligned}$$

$$T_{42} = \frac{1}{12} \sqrt{\frac{5}{7}} [1 - 2g^2 \sin^2 \delta + e^{2i\delta}]$$

$$T_{44} = -\frac{\sqrt{5}}{12} e^{2i\delta} \quad (\text{A.24})$$

For the quantities  $d_L$  corresponding to the analyzers  $\hat{n}, \hat{k}$  and  $\hat{q}$ , we have the following expressions:

$$d_2^{(n)} = \frac{1}{4} \frac{-0.5 + 2.8g + 2.2g^2}{1 + g + 0.7g^2}, \quad d_4^{(n)} = \frac{1}{4} \frac{-0.5 + 0.8g^2}{1 + g + 0.7g^2}$$

$$d_2^{(k)} = -\frac{1}{2} \frac{0.7 + 2.8g + g^2}{1 + g + 0.7g^2}, \quad d_4^{(k)} = \frac{0.2g^2}{1 + g + 0.7g^2}$$

$$d_2^{(q)} = 0.7 \frac{1 + g - 0.2g^2}{1 + g + 0.7g^2}, \quad d_4^{(q)} = 0. \quad (\text{A.25})$$

The  $g$ -dependence of the quantities  $d_2$  is shown in Fig. 2 together with the extreme  $d_2$  values. In Fig. 2 we also present the  $\rho_{00}$  spin density matrix element of the  $\rho^0$ -meson produced in the  $X^0 \rightarrow \gamma \rho^0$  decay which (in the helicity frame) takes the form

$$\rho_{00}^H = \frac{0.3}{1 + g + 0.7g^2} \quad (\text{A.26})$$

The experimental  $\rho_{00}$  value, shown also in Fig. 2, yields then the following estimates for the parameter  $g$ :  $g = 3.5_{-1.4}^{+1.4}$  and  $g = 2.0_{-1.3}^{+\infty}$ . Besides, the small negative  $g$  values are probably excluded by the anisotropy observed in the  $\hat{K} \hat{K}$  distribution  $^{11/}$  ( $P/E < 1$  implies  $d_2^{(k)} < 0$ ).

Fig. 2. The decay coefficients  $d_2$  vs the mixing parameter  $g$  of the E2 and M1 transition amplitudes in the  $X^0 \rightarrow \gamma \rho^0$  decay. The  $g$ -dependence of the  $\rho_{00}$ -density matrix element (helicity frame) of the  $\rho^0$ -meson produced in the  $X^0 \rightarrow \gamma \rho^0$  decay is presented as well.
