More than 50 new inhabitants of the predicted "Island of stability" of the superheavy elements have been observed in the experiments using accelerated ${ }^{48} \mathrm{Ca}$ ions and targets ranging from ${ }^{235} \mathrm{U}$ to ${ }^{251} \mathrm{Cf}$. The determined decay properties of all the observed isotopes indicate increase of their life-times with approach to the hypothetic closed neutron shell $N=184$ [1]. However, the heaviest nuclei synthesized by now, ${ }^{294} \mathrm{Ts}(Z=117)$ and ${ }^{294} \mathrm{Og}(Z=118)$, have 177 and 176 neutrons [2,3] and are still 7 and 8 neutrons apart from $N=184$.

This work reviews experimental studies that have been performed employing the DGFRS (JINR, Dubna) and resulted in production of the heaviest ${ }^{294} \mathrm{Ts}$ and ${ }^{294} \mathrm{Og}$ in the most recent experiments. Future possibilities of synthesizing new nuclides in the region of SHEs with higher $Z$ (119 and 120), as well as of more neutron-rich isotopes of $\mathrm{Lv}, \mathrm{Ts}$, and Og nuclei are discussed.
